A B S T R A C T

Plant tissue culture is a modern biotechnological technique that plays a significant role in improving agricultural productivity and sustainability. It involves the growth of plant cells, tissues, or organs under sterile and controlled laboratory conditions. This technique enables the rapid multiplication of disease-free, genetically uniform, and high-quality planting materials throughout the year. Tissue culture has wide applications in the propagation of economically important crops such as banana, sugarcane, potato, rice, and ornamental plants. It also supports crop improvement, conservation of rare and endangered plant species, production of disease-resistant varieties, and preservation of valuable genetic resources. By reducing dependence on traditional propagation methods, tissue culture contributes to increased crop yield, improved quality, and sustainable agricultural development. Thus, plant tissue culture serves as a promising tool for cultivating the future of agriculture and ensuring global food security.

1. INTRODUCTION

With the increased levels of climate change in the world and the population at all-time highs, modern agriculture is presented with an existential crisis, which revolves around the provision of sustainable food production without undermining the diminishing natural resources and biological diversity (Vardhan *et al*., 2021). High dependency on inputs in agriculture usually leads to deterioration in soil health and genetic diversity in the crop species, hence presenting a major problem for the smallholder farmers in developing countries (Ude *et. al*., 2025; Thakur, *et. al*., 2024).

There are many cases where farmers in the tropical regions growing staple foods such as yam, plantain, and cassava have problems with accessing planting material due to seasonal problems. The farmer would be required historically to set aside a good percentage of the crops as seed material for the next farming season, hence increasing food scarcity. In addition, the process causes a continuous transmission of the pathogens from one season to another, thus reducing the yields (Vardhan *et al*., 2025). Plant Tissue Culture (PTC) refers to the aseptic culture of plant cells, tissues, or organs on nutrient-rich media, which is a definite solution to this problem.

2. CORE BIOLOGICAL PRINCIPLES & LABORATORY WORKFLOW

The key foundation of plant tissue culture is the concept of cellular totipotency, which is the basic

biological theory proposed by G. Haberlandt way back in 1902. Cellular totipotency states that each and every plant cell contains all the genetic information required for the regeneration of a complete plant, when supplied with adequate nutrition and phytohormones (Mounika *et al*., 2025). The industrial usage of PTC involves five distinct phases (Thakur, *et. al*., 2024).

Stage 0: Explant Selection & Surface Sterilization; **Stage 1:** Culture Initiation & Establishment; **Stage 2:** Shoot Multiplication *via* Phytohormones; **Stage 3:** Root Induction & Subculturing; **Stage 4:** Ex Vitro Hardening & Acclimatization

During the whole process, environmental parameters like temperature (25 ± 2°C), humidity (50-60%), daylength and balance of nutrients (macronutrients, micronutrients, vitamins, amino acids, sucrose and agar) are strictly controlled [2]. Meristem shoots are always chosen as explants because of the high frequency of cell division and absence of vascular connections which make them free from virus infections (Ude *et. al*., 2025).

3. APPLICATIONS & IMPACT ACROSS AGRICULTURE

The practice of plant tissue culture has transcended its original purpose in botany to become an essential industry that helps ensure the world's food supply, horticulture, and forestry (Ude *et. al*., 2025).

3.1 Mass Micro propagation & Year-Round Planting

The vegetative propagation method for banana, plantain, potato, and cassava crops involves the use of suckers and tubers which are slow processes and have a very high chance of spreading deadly diseases like BBTV or Fusarium wilt. The PTC process enables thousands of disease-free and genetically similar plantlets to be produced from a single superior quality mother plant in months. This will save small-scale farmers from the constraint of seasonality, allowing them to eat and sell all the harvested products while depending on tissue culture planting materials (Ude *et. al*., 2025).

3.2 Somatic Embryogenesis & Synthetic Seeds

The process of somatic embryogenesis is that of forming embryonic bodies through non-zygotic somatic cells, which include leaves, petioles, or roots, hence, sidestepping sexual propagation as well as overcoming seed dormancy problems (Mounika *et al*., 2024). The somatic embryos can be wrapped up in calcium alginate matrices to produce artificial or synthetic seeds. The use of synthetic seeds ensures convenient handling, storage, transportation, and direct planting in the field (Bhusare, 2022).

3.3 Horticulture, Floriculture & High-Value Crops

For the floriculture industry in the world, commercial labs make extensive use of the process of tissue culture to satisfy the huge demand of consumers for ornamental plants such as orchids, gerberas, roses, lilies, and anthuriums. Fruit trees of high value such as strawberries, papayas, pineapples, and avocados are also propagated using PTC to ensure elite fruit quality and rapid canopy establishment (Bhusare, 2022).

"*In tissue culture, small farmers no longer have to keep their harvests for planting purposes. An explant of the mother plant can be multiplied into thousands of disease-free plantlets, doubling the yields.*"

3.4 Crop Improvement & Genetic Engineering

PTC plays a crucial role in offering a cellular basis for developing plant breeding technologies. Somaclonal variation refers to the development of new crop types as a result of spontaneous genetic changes during callus stage culture. These crops have better resistance to stress (Ude *et. al*., 2025; Bhusare, 2022). Embryo rescue technique makes it possible for breeders to hybridize sexually incompatible distantly related wild relatives by rescuing their embryos. Moreover, double-haploids can be generated using anther/microspore culture within no time (Bhusare, 2022).

4. MAJOR BOTTLENECKS IN TRADITIONAL PTC

While classical tissue culture is extremely beneficial, it faces technical and economic difficulties that prevent widespread application (Ude *et. al*., 2025; Thakur *et. al*., 2024).

Challenge	Cause / Mechanism	Agricultural Impact
Microbial Contamination	Bacterial/ fungal ingress in culture media	Loss of entire culture batches; high cleanroom costs (Ude *et. al*., 2025; Thakur *et. al*., 2024)
Phenolic Browning & Recalcitrance	Lethal oxidation of tissue exudates; refusal to regenerate	Prevents micropropagation of woody and elite cereal varieties (Ude *et. al*., 2025; Quiroz *et. al*., 2025)

Soma clonal Variation	Unintended genetic/epigenetic alterations during callus phase	Loss of clonal fidelity and reduced fruit uniformity (Ude *et. al*., 2025; Quiroz *et. al*., 2025)
High Capital Requirements	Expensive growth rooms, climate control, and skilled labor	Priced out of reach for resource-poor smallholder communities (Ude *et. al*., 2025; Thakur *et. al*., 2024)

5. THE PARADIGM SHIFT: TISSUE CULTURE-INDEPENDENT (TCI) TECHNOLOGIES

In order to reduce dependency on costly aseptic facilities and overcome genotypic recalcitrance, plant biotechnology is developing Tissue Culture Independent (TCI) transformation and genome editing technologies (Mounika *et al*., 2022). Through direct manipulation of plant germline or meristem cells, TCI approaches skip the in vitro callus stage completely (Quiroz *et. al*., 2025).

De Novo Meristem Induction: The transient induction of developmental regulator (DR) genes (WUSCHEL2, SHOOT MERISTEMLESS, IPT) directly reprograms somatic stem cells in an adult plant grown in the soil into growing new shoots without tissue culture (Quiroz *et. al*., 2025).

Virus-Induced Genome Editing (VIGE): Vectors like TRV, BSMV have CRISPR gRNAs tagged with mobility signals (such as FT mRNA) which move to faraway places within shoot apical meristems, thus providing gene editing right inside the seed itself (Quiroz *et. al*., 2025).

Grafting-Mediated Editing: The integration of Cas9 mRNA and gRNA in mobile tRNA-like structure (TLS) in a transgenic rootstock enables movement of editing signals upwards through non-transgenic scions to form transgene free edited seeds (Quiroz *et. al*., 2025).

Pollen Magnetofection & Floral Dip: Use of magnetic nanoparticles containing CRISPR/DNA attached to pollen grains allows for direct fertilization and production of transgenic seeds without the need for laboratory regeneration (Quiroz *et. al*., 2025).

6. CONCLUSION

Plant Tissue Culture has transformed itself from a landmark development in botany in the 20th century to a driving force in contemporary agricultural sustainability. Through providing disease-free and high-yield planting material, PTC helps poor communities to overcome hunger while replicating quality crop varieties around the world. With continuous advances in TCI technologies, the democratization of genetic engineering of plants will be further facilitated in the coming years.
